We determine conditions for the presence of stochastic resonance in a lossy bosonic channel with a nonlinear, threshold decoding. The stochastic resonance noise benefit occurs if and only if the detection threshold is outside of a “forbidden interval.” We show how noise benefits can occur in different settings: when transmitting classical messages through a lossy bosonic channel, when transmitting over an entanglement-assisted lossy bosonic channel, and when discriminating channels with different loss parameters. Moreover, we consider a setting in which noise can benefit the faithful transmission of a qubit over a lossy bosonic channel with a particular encoding and decoding. In the latter case, we measure noise benefits in terms of the average channel fidelity and the entanglement preserved between a reference system and the channel output. In all cases, we assume Gaussian noise, allowing us to improve upon the forbidden-interval conditions found in earlier work.

Keywords: stochastic resonance, quantum communication, channel discrimination, entanglement-assisted communication

I. INTRODUCTION

It is common wisdom to consider noise as a nuisance. This is especially the case in quantum information science [23, 31], where noise is often an obstacle to the robust implementation of quantum information processing protocols. However, the idea that noise can sometimes play a constructive role has recently started to penetrate this field. The so-called *stochastic resonance* (SR) effect is the most common example of this kind [9, 12, 14, 18, 21], and it can be present in biological systems [7, 19, 20, 29]. SR occurs in a nonlinear system when noise benefits the system. It can take place in both classical and quantum systems that use noise to help detect faint signals. In a quantum communication setting, this possibility has been put forward in Refs. [3, 4] and more recently in Refs. [10, 30, 32]. It is important to determine general criteria for the occurrence of SR in quantum information protocols.

Continuous variable systems are usually confined to Gaussian states and processes, and SR effects are not expected in any linear processing of such systems. However, information is often available in digital (discrete) form, and therefore it must be subject to “dequantization” at the input of a continuous Gaussian channel and “quantization” at the output [15, 27]. These processes are usually involved in the conversion of digital to analog signals and vice versa. Since these mappings are few-to-many and many-to-few, they are inherently non-linear, and we can thus expect the occurrence of the SR effect in this case. The simplest model representing such a situation is one in which two bit values are encoded into the positive and negative parts of a real continuous alphabet and subsequently decoded by a threshold detection [19]. In the quantum framework, the continuous alphabet is realized by coherent-state amplitudes [6, 13].

Hence, we shall consider a bit encoded into squeezed-

coherent states with different amplitudes that are subsequently sent through a Gaussian quantum channel (specifically, a lossy bosonic channel [11]). At the output, the states are subjected to threshold measurement of their amplitude. In addition to such a setting, we shall consider one involving entanglement shared by a sender and receiver as well as one involving quantum channel discrimination. Finally, we also consider a quantum communication setting. For all of these settings, we determine conditions for the occurrence of the SR effect. These appear as forbidden intervals for the threshold detection values, in analogy with the results of Refs. [19, 32] that are here extended to other schemes.

II. NOISE BENEFITS IN CLASSICAL COMMUNICATION

Let us consider a lossy bosonic quantum channel with transmissivity $\eta \in (0, 1)$ [11, 16]. Our aim is to evaluate the probability of successful decoding, considered as a performance quantifier, when sending classical information through such a channel.

Let us suppose that the sender uses as input a displaced and squeezed vacuum. Working in the Heisenberg picture, the input variable of the communication setup is expressed by the operator:

$$\hat{q}e^{-r} - \alpha_q(-1)^X, \quad (1)$$

encoding a bit value $X \in \{0, 1\}$, where $\hat{q}$ is the position quadrature operator, $\alpha_q \in \mathbb{R}_+$ is the displacement amplitude, and $r \geq 0$ is the squeezing parameter [13].

The output observable resulting from sending the above state through a lossy bosonic channel with transmissivity η is as follows [16]:

$$\sqrt{\eta}(-\alpha_q(-1)^X + \hat{q}e^{-r}) + \sqrt{1-\eta}\hat{q}_E,$$

where $\hat{q}_E$ is the position quadrature operator of an environment mode (assumed to be in the vacuum state for the sake of simplicity).

At the receiver's end, let us consider the possibility of adding a random, Gaussian-distributed displacement $\nu_q \in \mathbb{R}$ to the arriving state. Then, the output observable becomes as follows:

$$\sqrt{\eta}(-\alpha_q(-1)^X + \hat{q}e^{-r}) + \sqrt{1-\eta}\hat{q}_E + \nu_q.$$

Upon measurement of the position quadrature operator, the following signal value S_X results

$$S_X = \sqrt{\eta}(-\alpha_q(-1)^X + qe^{-r}) + \sqrt{1-\eta}q_E + \nu_q. \quad (2)$$

Following Ref. [32], we define a random variable summing up all noise terms:

$$N \equiv \sqrt{\eta}qe^{-r} + \sqrt{1-\eta}q_E + \nu_q. \quad (3)$$

Let $\mathcal{N}(\mu, \sigma^2)$ denote the density for a Gaussian random variable with mean μ and variance σ^2 :

$$\mathcal{N}(\mu, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left\{-\frac{(x-\mu)^2}{2\sigma^2}\right\}.$$

The density $P_N(n)$ of random variable N is then as follows:

$$P_N(n) = \mathcal{N}(0, \eta e^{-2r}/2) \circ \mathcal{N}(0, \sigma^2/2) \circ \mathcal{N}(0, (1-\eta)/2), \quad (4)$$

where $\circ$ denotes convolution. The density $P_N(n)$ is a convolution because random variables qe^{-r} , ν_q , and q_E are independent.

Notice that the noise term (3) does not depend on the encoded value X and neither does its probability density. From (4) we explicitly get

$$P_N(n) = \mathcal{N}(0, (1-\eta + \sigma^2 + \eta e^{-2r})/2). \quad (5)$$

The output signal (2) can now be written as

$$S_X = -\sqrt{\eta}\alpha_q(-1)^X + N.$$

The receiver then thresholds the measurement result with a threshold $\theta \in \mathbb{R}$ to retrieve a random bit Y where

$$Y \equiv H(-\sqrt{\eta}\alpha_q(-1)^X + N - \theta), \quad (6)$$

and H is the Heaviside step function defined as $H(x) = 1$ if $x \geq 0$ and $H(x) = 0$ if $x < 0$.

To evaluate the probability of successful decoding, we compute the conditional probabilities

$$\begin{aligned} P_{Y|X}(0|0) &= \int_{-\infty}^{+\infty} [1 - H(-\sqrt{\eta}\alpha_q + n - \theta)] P_N(n) \, dn \\ &= 1 - P_{Y|X}(1|0), \end{aligned} \quad (7)$$

$$\begin{aligned} P_{Y|X}(1|1) &= \int_{-\infty}^{+\infty} H(\sqrt{\eta}\alpha_q + n - \theta) P_N(n) \, dn \\ &= 1 - P_{Y|X}(0|1). \end{aligned} \quad (8)$$

Using (5), we find

$$\begin{aligned} P_{Y|X}(0|0) &= \frac{1}{2} + \frac{1}{2} \operatorname{erf}\left[\frac{\theta + \alpha_q\sqrt{\eta}}{\sqrt{1-\eta + \sigma^2 + \eta e^{-2r}}}\right], \\ P_{Y|X}(1|1) &= \frac{1}{2} - \frac{1}{2} \operatorname{erf}\left[\frac{\theta - \alpha_q\sqrt{\eta}}{\sqrt{1-\eta + \sigma^2 + \eta e^{-2r}}}\right], \end{aligned}$$

where $\operatorname{erf}(z)$ denotes the error function:

$$\operatorname{erf}(z) \equiv \frac{2}{\sqrt{\pi}} \int_0^z \exp\{-x^2\} \, dx.$$

This situation is identical to the one treated in Ref. [32], and the forbidden interval can be determined in a simple way by looking at the probability of successful decoding (note that others have also considered the probability-of-success (or error) criterion [24, 26]). The probability of success is defined as

$$P_s \equiv P_X(0)P_{Y|X}(0|0) + P_X(1)P_{Y|X}(1|1). \quad (9)$$

Setting $P_X(0) = \wp$ and $P_X(1) = (1 - \wp)$, the probability of success is as follows:

$$\begin{aligned} P_s &= \frac{1}{2} + \frac{1}{2}\wp \operatorname{erf}\left(\frac{\theta + \sqrt{\eta}\alpha_q}{\sqrt{1-\eta + \sigma^2 + \eta e^{-2r}}}\right) \\ &\quad - \frac{1}{2}(1-\wp) \operatorname{erf}\left(\frac{\theta - \sqrt{\eta}\alpha_q}{\sqrt{1-\eta + \sigma^2 + \eta e^{-2r}}}\right). \end{aligned} \quad (10)$$

Our goal is to find the maximum of (10) over α_q , r , θ for fixed η and see how it changes as a function of σ . This leads us to the following proposition:

Proposition 1 (The forbidden interval) *The probability of success P_s shows a non-monotonic behavior versus σ iff $\theta \notin [\theta_-, \theta_+]$, where $\theta_{\pm}$ are the two roots of the following equation:*

$$\frac{\wp(\sqrt{\eta}\alpha_q + \theta)}{(1-\wp)(-\sqrt{\eta}\alpha_q + \theta)} = \exp\left[\frac{4\sqrt{\eta}\alpha_q\theta}{1-\eta + e^{-2r}\eta}\right], \quad (11)$$

such that $\theta_- \leq -\alpha_q\sqrt{\eta} < \alpha_q\sqrt{\eta} \leq \theta_+$.

Proof. We consider P_s as a function of σ^2 . In order to have a non-monotonic behavior for $P_s(\sigma^2)$, we must check for the presence of a maximum. By imposing

$$\frac{dP_s(\sigma^2)}{d\sigma^2} = 0 \quad (12)$$

we obtain Eq. (11). Two necessary conditions for this equation to admit a solution are

$$\theta > \sqrt{\eta}\alpha_q, \quad (13)$$

and

$$\left(\frac{1-\wp}{\wp}\right) \left(\frac{\theta - \sqrt{\eta}\alpha_q}{\theta + \sqrt{\eta}\alpha_q}\right) \leq 1. \quad (14)$$

FIG. 1: The probability of success P_s (corresponding to the choice $\varphi = 1/2$) versus σ , for the noise-assisted threshold detection. The values of the parameters are $\eta = 0.8$, $\alpha_q = 1$ and $r = 0$, giving $\theta_{\pm} \approx \pm 0.95$ after applying Proposition 1. Curves from top to bottom correspond respectively to $\theta = 1.35, 1.25, 1.15, 1.05, 0.95, 0.85$. Due to symmetry, we also have the same plot for the values $\theta = -1.35, -1.25, -1.15, -1.05, -0.95, -0.85$.

Explicitly the critical value of σ^2 , for which (12) is satisfied, reads

$$\sigma_*^2 = -1 + \eta - e^{-2r}\eta + \frac{4\sqrt{\eta}\alpha_q\theta}{\ln[\varphi(\sqrt{\eta}\alpha_q + \theta)/(1-\varphi)(-\sqrt{\eta}\alpha_q + \theta)]}. \quad (15)$$

An inspection of Eq. (11), shows that σ_*^2 is positive iff either $\theta < \theta_-$ or $\theta > \theta_+$, where $\theta_{\pm}$ are the two roots of the equation $\sigma_*^2 = 0$. Because of the condition (13), they are such that $\theta_- \leq -\alpha_q\sqrt{\eta} < +\alpha_q\sqrt{\eta} \leq \theta_+$.

Conversely, if $\theta < \theta_-$ or $\theta > \theta_+$, it follows that $\sigma_*^2 > 0$, and hence $P_s(\sigma^2)$ is non-monotonic. ■

The above proposition improves upon the theorem from Ref. [32] in several important ways, due to the assumption that the noise is Gaussian, allowing us to analyze it more carefully. First, (15) gives the optimal value of the noise that leads to the maximum success probability if the threshold is outside of the forbidden interval (though, note that other works have algorithms to learn the optimal noise parameter [22]). Second, there is no need to consider an infinite-squeezing limit, as was the case in Ref. [32], in order to guarantee the non-monotonic signature of SR. Finally, the theorem demonstrates that SR can occur for both subthreshold and suprathreshold [28] signals, whereas the theorems from Ref. [32] apply only to subthreshold signals.

As an example, Figure 1 shows the probability of success P_s as a function of σ for various values of the threshold θ around the high signal level $\alpha_q\sqrt{\eta}$. Identical behavior can be found for values of θ around the low signal level $-\alpha_q\sqrt{\eta}$.

Figure 2 plots the forbidden interval in the θ, r plane. We can see that increasing the squeezing level reduces

FIG. 2: Forbidden interval (area between upper and lower curves) in the θ, r plane. The top (resp. bottom) solid line corresponds to θ_+ (resp. θ_-) while the top (resp. bottom) dashed line corresponds to $\sqrt{\eta}\alpha_q$ (resp. $-\sqrt{\eta}\alpha_q$). The values of the other parameters are $\varphi = 1/2$, $\eta = 0.8$, and $\alpha_q = 1$.

the width of the forbidden interval up to $2\sqrt{\eta}\alpha_q$. Similarly, Figure 3 plots the forbidden interval in the θ, α_q plane. Increasing the amplitude enlarges the width of the forbidden interval up to $2\sqrt{\eta}\alpha_q$.

III. NOISE BENEFITS IN ENTANGLEMENT-ASSISTED CLASSICAL COMMUNICATION

Let us consider the same channel as in the previous section, but we now assume that the sender and receiver share an entangled state, namely, a two-mode squeezed vacuum [13], before communication begins. This situation is somewhat similar to the communication scenario in super-dense coding [2, 5], with the exception that we have continuous variable systems and thresholding at the receiver. Let mode 1 (resp. 2) belong to the sender (resp. receiver). The sender displaces her share of the entanglement by the complex number $-\alpha_q(-1)^{X_q} - i\alpha_p(-1)^{X_p}$ in order to transmit the two bits X_q and X_p . The resulting displaced squeezed vacuum operators are as follows:

$$(\hat{q}_1 - \hat{q}_2)e^{-r} - \alpha_q(-1)^{X_q}, \quad (16)$$

$$(\hat{p}_1 + \hat{p}_2)e^{-r} - \alpha_p(-1)^{X_p}, \quad (17)$$

where $\hat{q}, \hat{p}$ are the position, momentum quadrature operators, $r \geq 0$ is the squeezing strength, $\alpha_q, \alpha_p \in \mathbb{R}$ are

FIG. 3: Forbidden interval (area between upper and lower curves) in the θ, α_q plane. The top (resp. bottom) solid line corresponds to θ_+ (resp. θ_-), while the top (resp. bottom) dashed line corresponds to $\sqrt{\eta}\alpha_q$ (resp. $-\sqrt{\eta}\alpha_q$). The values of the other parameters are $\wp = 1/2$, $\eta = 0.8$, and $r = 0$.

the displacement amplitudes, and $X_q, X_p \in \{0, 1\}$ are bit value random variables.

Since $\hat{q}_1 - \hat{q}_2$ commutes with $\hat{p}_1 + \hat{p}_2$, it suffices to analyze the output for (16). After the sender transmits her share of the entanglement through a lossy bosonic channel with transmissivity $\eta \in (0, 1)$, the operator describing their state is as follows:

$$(\sqrt{\eta}\hat{q}_1 - \hat{q}_2)e^{-r} - \sqrt{\eta}\alpha_q(-1)^{X_q} + \sqrt{1-\eta}\hat{q}_E,$$

where $\hat{q}_E$ is the position quadrature operator of the environment mode (assumed to be in the vacuum state for the sake of simplicity).

At the receiver's end, let us again consider the possibility of adding a random, Gaussian-distributed displacement $\nu_q \in \mathbb{R}$ to the arriving state. Then the output observable becomes as follows:

$$(\sqrt{\eta}\hat{q}_1 - \hat{q}_2)e^{-r} - \sqrt{\eta}\alpha_q(-1)^{X_q} + \sqrt{1-\eta}\hat{q}_E + \nu_q.$$

Repeating the steps of Section II, we have

$$S_{X_q} = -\sqrt{\eta}\alpha_q(-1)^{X_q} + N,$$

where now

$$N \equiv (\sqrt{\eta}\hat{q}_1 - \hat{q}_2)e^{-r} + \sqrt{1-\eta}\hat{q}_E + \nu_q. \quad (18)$$

and

$$P_N(n) = \mathcal{N}(0, \eta e^{-2r}/2) \circ \mathcal{N}(0, e^{-2r}/2) \circ \mathcal{N}(0, \sigma_q^2/2) \circ \mathcal{N}((1-\eta)/2), \quad (19)$$

so that

$$P_N(n) = \mathcal{N}(0, (1-\eta + \sigma_q^2 + (1+\eta)e^{-2r})/2). \quad (20)$$

The receiver then thresholds the measurement result with a threshold $\theta_q \in \mathbb{R}_+$, and he retrieves a random bit Y_q where

$$Y_q \equiv H(-\sqrt{\eta}\alpha_q(-1)^{X_q} + N - \theta_q), \quad (21)$$

and H is the unit Heaviside step function.

Proceeding as in Section II, we obtain the following input/output conditional probabilities

$$P_{Y_q|X_q}(0|0) = \frac{1}{2} + \frac{1}{2}\text{erf}\left[\frac{\theta_q + \alpha_q\sqrt{\eta}}{\sqrt{1-\eta + \sigma_q^2 + (1+\eta)e^{-2r}}}\right],$$

$$P_{Y_q|X_q}(1|1) = \frac{1}{2} - \frac{1}{2}\text{erf}\left[\frac{\theta_q - \alpha_q\sqrt{\eta}}{\sqrt{1-\eta + \sigma_q^2 + (1+\eta)e^{-2r}}}\right].$$

Then, writing $P_{X_q}(0) = \wp_q$ and $P_{X_q}(1) = 1 - \wp_q$, the probability of success reads

$$P_{s,q} = \frac{1}{2} + \frac{1}{2}\wp_q \text{erf}\left(\frac{\theta_q + \sqrt{\eta}\alpha_q}{\sqrt{1-\eta + \sigma_q^2 + (1+\eta)e^{-2r}}}\right) - \frac{1}{2}(1 - \wp_q) \text{erf}\left(\frac{\theta_q - \sqrt{\eta}\alpha_q}{\sqrt{1-\eta + \sigma_q^2 + (1+\eta)e^{-2r}}}\right). \quad (22)$$

Analogously, for the quadrature $\hat{p}_1 + \hat{p}_2$, we have

$$P_{s,p} = \frac{1}{2} + \frac{1}{2}\wp_p \text{erf}\left(\frac{\theta_p + \sqrt{\eta}\alpha_p}{\sqrt{1-\eta + \sigma_p^2 + (1+\eta)e^{-2r}}}\right) - \frac{1}{2}(1 - \wp_p) \text{erf}\left(\frac{\theta_p - \sqrt{\eta}\alpha_p}{\sqrt{1-\eta + \sigma_p^2 + (1+\eta)e^{-2r}}}\right). \quad (23)$$

We have assumed that the noise terms added to the quadratures $\hat{q}_1 - \hat{q}_2$ and $\hat{p}_1 + \hat{p}_2$ have variances σ_q^2 and σ_p^2 respectively.

We finally arrive at the following proposition:

Proposition 2 (The forbidden rectangle) *The probability of success $P_s = P_{s,q}P_{s,p}$ shows a non-monotonic behavior vs σ_q, σ_p iff $\theta_q \notin [-\theta_{q-}, \theta_{q+}]$ or $\theta_p \notin [-\theta_{p-}, \theta_{p+}]$ where $\theta_{\bullet\pm}$ are the roots of the following equation:*

$$\frac{\wp_{\bullet}(\sqrt{\eta}\alpha_{\bullet} + \theta_{\bullet})}{(1 - \wp_{\bullet})(-\sqrt{\eta}\alpha_{\bullet} + \theta_{\bullet})} = \exp\left[\frac{4\sqrt{\eta}\alpha_{\bullet}\theta_{\bullet}}{1 - \eta + (1 + \eta)e^{-2r}}\right],$$

such that $\theta_{\bullet-} \leq -\alpha_{\bullet}\sqrt{\eta} < +\alpha_{\bullet}\sqrt{\eta} \leq \theta_{\bullet+}$ (here $\bullet$ stands for either q or p).

Proof. If we consider the probability of success as function of σ_q^2 and σ_p^2 , in order to have a non-monotonic behavior for $P_s(\sigma_q^2, \sigma_p^2)$ we must check for the presence of a maximum in either the σ_q^2 or σ_p^2 variable. By solving

$$\frac{\partial P_s(\sigma_q^2, \sigma_p^2)}{\partial \sigma_q^2} = P'_{s,q}P_{s,p} = 0, \quad (24)$$

we get (provided $P_{s,p} > 0$)

$$\sigma_{q*}^2 = -1 + \eta - (1 + \eta)e^{-2r} + \frac{4\sqrt{\eta}\alpha_q\theta_q}{\ln \left[\frac{\wp_q(\sqrt{\eta}\alpha_q + \theta_q)}{(1 - \wp_q)(\theta_q - \sqrt{\eta}\alpha_q)} \right]}.$$

It must be that $\sigma_{q*}^2 > 0$ because this parameter is the variance of the noise. This is realized when either $\theta < \theta_-$ or $\theta > \theta_+$, where $\theta_{\pm}$ are the two roots of the equation $\sigma_{q*}^2 = 0$ such that $\theta_- \leq -\alpha_q\sqrt{\eta} < +\alpha_q\sqrt{\eta} \leq \theta_+$.

Conversely, if $\theta < \theta_-$ or $\theta > \theta_+$ it follows that $\sigma_{q*}^2 > 0$, hence P_s is non monotonic.

Analogous reasonings hold for the maximum in σ_p^2 . ■

It is worth remarking in the above proposition that either of the conditions $\theta_q \notin [-\theta_{q-}, \theta_{q+}]$ or $\theta_p \notin [-\theta_{p-}, \theta_{p+}]$ (or both) have to be satisfied in order to have a non monotonic behavior for P_s . This follows because P_s is a function of two variables σ_q^2 and σ_p^2 , hence it suffices that the partial derivative with respect to one of them has a maximum to have a non-monotonic behavior. As consequence we have a “forbidden rectangle” rather than “forbidden stripes” in the θ_q, θ_p plane.

It is also worth noticing the difference of the equation in the above proposition with that in the proposition of the previous section. Here the squeezing factor e^{-2r} is multiplied by $(1 + \eta)$ rather than simply η . This is because we now have two squeezed modes, one of which is attenuated by the lossy channel.

IV. NOISE BENEFITS IN CHANNEL DISCRIMINATION

Let us now consider two lossy quantum channels with transmissivities $\eta_0, \eta_1 \in (0, 1)$ (suppose wlog $\eta_0 > \eta_1$). Our aim is to distinguish them. Then, suppose to use as probe (input) a squeezed and displaced vacuum operator

$$\hat{q}e^{-r} + \alpha_q, \quad (25)$$

where $\hat{q}$ is the position quadrature operator, r is the squeezing parameter, and $\alpha_q \in \mathbb{R}$ the displacement amplitude.

The transmission through the lossy channel with transmissivity η_X , $X = 0, 1$, can be considered as the encoding of a bit value random variable $X = 0, 1$ occurring with probability P_X . The output observable after transmission is then

$$\sqrt{\eta_X}(\alpha_q + \hat{q}e^{-r}) + \sqrt{1 - \eta_X}\hat{q}_E,$$

where $\hat{q}_E$ is the position quadrature operator of the environment mode (assumed to be in the vacuum state for the sake of simplicity).

At the receiver's end, let us consider the possibility of adding a random, Gaussian-distributed displacement $\nu_q \in \mathbb{R}$ to the arriving state. Then the output observable becomes

$$\sqrt{\eta_X}(\alpha_q + \hat{q}e^{-r}) + \sqrt{1 - \eta_X}\hat{q}_E + \nu_q.$$

Upon measurement of the position quadrature operator, the signal value is

$$S_X = \sqrt{\eta_X}(\alpha_q + qe^{-r}) + \sqrt{1 - \eta_X}q_E + \nu_q. \quad (26)$$

We define a conditional random variable $N|X$ summing all noise terms:

$$N|X \equiv \sqrt{\eta_X}qe^{-r} + \sqrt{1 - \eta_X}q_E + \nu_q. \quad (27)$$

The density $P_{N|X}(n|x)$ of random variable $N|X$ is

$$P_{N|X}(n|x) = \mathcal{N}(0, \eta_x e^{-2r}/2) \circ \mathcal{N}(0, \sigma^2/2) \circ \mathcal{N}(0, (1 - \eta_x)/2). \quad (28)$$

Notice that the noise term (27) explicitly depends on the encoded value X and so does its probability density. From (28), we explicitly obtain

$$P_{N|X}(n|x) = \mathcal{N}(0, (1 - \eta_x + \sigma^2 + \eta_x e^{-2r})/2). \quad (29)$$

The output signal (26) can now be written as

$$S_X = \sqrt{\eta_X}\alpha_q + N|X.$$

The receiver then thresholds the measurement result with a threshold $\theta \in \mathbb{R}_+$ to retrieve a random bit Y where

$$Y \equiv H(\theta - \sqrt{\eta_X}\alpha_q - N|X),$$

and H is the unit Heaviside step function. In this case, the receiver assigns $Y = 1$ if the threshold θ is larger than the output signal S_X , and he assigns $Y = 0$ if it is less than the signal value.

The final detected bit Y should be the same as the encoded bit X . Hence, the probability of success reads like (9) where now

$$P_{Y|X}(0|0) = \int_{-\infty}^{+\infty} [1 - H(\theta - \sqrt{\eta_0}\alpha_q - n)] P_{N|X}(n|0) dn,$$

$$P_{Y|X}(1|1) = \int_{-\infty}^{+\infty} H(\theta - \sqrt{\eta_1}\alpha_q - n) P_{N|X}(n|1) dn.$$

Using (29) we obtain

$$P_{Y|X}(0|0) = \frac{1}{2} \left[1 - \operatorname{erf} \left(\frac{\theta - \sqrt{\eta_0}\alpha_q}{\sqrt{1 - \eta_0 + \sigma^2 + \eta_0 e^{-2r}}} \right) \right],$$

$$P_{Y|X}(1|1) = \frac{1}{2} \left[1 + \operatorname{erf} \left(\frac{\theta - \sqrt{\eta_1}\alpha_q}{\sqrt{1 - \eta_1 + \sigma^2 + \eta_1 e^{-2r}}} \right) \right].$$

Then, writing $P_X(0) = \wp$ and $P_X(1) = 1 - \wp$, we get

$$P_s = \frac{1}{2} - \frac{1}{2}\wp \operatorname{erf} \left(\frac{\theta - \sqrt{\eta_0}\alpha_q}{\sqrt{1 - \eta_0 + \sigma^2 + \eta_0 e^{-2r}}} \right) + \frac{1}{2}(1 - \wp) \operatorname{erf} \left(\frac{\theta - \sqrt{\eta_1}\alpha_q}{\sqrt{1 - \eta_1 + \sigma^2 + \eta_1 e^{-2r}}} \right). \quad (30)$$

Our goal is to find the maximum of (30) over α_q, r, θ for fixed η_0, η_1 and see how it changes as a function of σ^2 .

In the simplest case of $r = 0$, we have the following proposition:

Proposition 3 (The forbidden interval) *The probability of success P_s shows a non-monotonic behavior as a function of σ^2 iff $\theta \notin [\theta_-, \theta_+]$, where $\theta_{\pm}$ are the two roots of the following equation:*

$$\frac{\wp(\alpha_q \sqrt{\eta_0} - \theta)}{(1 - \wp)(\alpha_q \sqrt{\eta_1} - \theta)} = \exp \left[\alpha_q^2 (\eta_0 - \eta_1) - 2\alpha_q \theta (\sqrt{\eta_0} - \sqrt{\eta_1}) \right],$$

such that $\theta_- \leq \sqrt{\eta_1} \alpha_q < \sqrt{\eta_0} \alpha_q \leq \theta_+$.

Proof. We consider the probability of success as a function of σ^2 . In order to have a non-monotonic behavior for $P_s(\sigma^2)$, we must check for the presence of a maximum. By solving

$$\frac{dP_s(\sigma^2)}{d\sigma^2} = 0, \quad (31)$$

we obtain

$$\sigma_*^2 = -1 + \frac{\alpha_q^2 (\eta_0 - \eta_1) - 2\alpha_q \theta (\sqrt{\eta_0} - \sqrt{\eta_1})}{\ln \left[\wp(\sqrt{\eta_0} \alpha_q - \theta) / (1 - \wp)(\sqrt{\eta_1} \alpha_q - \theta) \right]}. \quad (32)$$

It must be the case that $\sigma_*^2 > 0$. By analyzing (32), we find that $\sigma_*^2 = 0$ admits two roots θ_- and θ_+ , such that $\theta_- \leq \sqrt{\eta_1} \alpha_q < \sqrt{\eta_0} \alpha_q \leq \theta_+$.

Conversely, if $\theta < \theta_-$ or $\theta > \theta_+$ it follows that $\sigma_*^2 > 0$. Hence $P_s(\sigma)$ is non-monotonic. ■

If $r \neq 0$, (31) is not algebraic—hence we did not succeed in providing an analytical expression for σ_*^2 . However, numerical investigations show a qualitative behavior of the forbidden interval's boundaries identical to that shown in Figures 2 and 3 (notice that here $-\sqrt{\eta} \alpha_q$ and $\sqrt{\eta} \alpha_q$ are replaced by $\sqrt{\eta_1} \alpha_q$ and $\sqrt{\eta_0} \alpha_q$, respectively).

V. NOISE BENEFITS IN QUANTUM COMMUNICATION

Let us now consider a setting in which a noise benefit can occur in the transmission of a qubit (Q). The aim is to first encode a qubit state into a bosonic mode state, send it through the lossy channel, and finally coherently decode, with a threshold mechanism, the output bosonic mode state into a qubit system at the receiving end. We should qualify that it is unclear to us whether one would actually exploit the encodings and decodings given in this section, but regardless, the setting given here provides a novel scenario in which a noise benefit can occur for a quantum system. We might consider the development in this section to be a coherent version of the settings in the previous sections. Also, it is in the spirit of a true “quantum stochastic resonance” effect hinted at in Ref. [8].

We work in the Schrödinger picture, and consider an initial state $|\varphi\rangle_Q \otimes |0\rangle_B$, where $|\varphi\rangle_Q = a|0\rangle_Q + b|1\rangle_Q$ is an arbitrary qubit state and $|0\rangle_B$ is the zero-eigenstate of the position-quadrature operator of the bosonic field.

Here for the sake of simplicity we are going to work with infinite-energy position eigenstates rather than with squeezed-coherent states.

Suppose that the encoding take place through the following unitary controlled-operations:

$$U_1^{QB} = |0\rangle_Q \langle 0| \otimes e^{-i\hat{p}_B x_0} + |1\rangle_Q \langle 1| \otimes e^{i\hat{p}_B x_0}, \quad (33)$$

$$U_2^{QB} = I_Q \otimes \int_{x \geq 0} |x\rangle_B \langle x| dx + X_Q \otimes \int_{x < 0} |x\rangle_B \langle x| dx, \quad (34)$$

with $\hat{p}_B$ the canonical momentum operator of the bosonic system, $|\pm x_0\rangle$ are the generalized eigenstate of the canonical position operator $\hat{q}_B$, and WLOG we assume $x_0 \in \mathbb{R}_+$. This encoding is the coherent version of encoding a binary number into an analog signal.

The effect of such operations on the initial states is

$$U_2^{QB} U_1^{QB} |\varphi\rangle_Q \otimes |0\rangle_B = |0\rangle_Q \otimes (a|x_0\rangle_B + b|-x_0\rangle_B).$$

Now, with the bosonic mode state factored out from the qubit state, it can be sent through the lossy channel. For the sake of analytical investigation, we consider a channel with unit trasmittivity (an identity channel). Then, the output state simply reads

$$\rho_B = (a|x_0\rangle + b|-x_0\rangle)_B (\bar{a}\langle x_0| + \bar{b}\langle -x_0|),$$

At this point we consider the possibility of adding Gaussian noise before the (threshold) decoding stage. This is modeled as a Gaussian-modulated displacement of the quadrature $\hat{q}_B$. The resulting state will be

$$\rho_{B'} = \int dq G_{\sigma^2}(q) D(q, 0) \rho_B D^\dagger(q, 0), \quad (35)$$

where $D(q, 0)$ is the displacement operator (displacing only in the $\hat{q}_B$ direction), and $G_\sigma(q)$ is a zero-mean, normalized Gaussian random variable with variance σ^2 .

Now, the state $\rho_{B'}$ is decoded into a qubit system Q' initially prepared in the state $|0\rangle_{Q'}$ through the following controlled-unitary operations involving a coherent threshold mechanism

$$V_1^{Q'B'} = I_Q \otimes \int_{x \geq \theta} |x\rangle_B \langle x| dx + X_Q \otimes \int_{x < \theta} |x\rangle_B \langle x| dx, \quad (36)$$

$$V_2^{Q'B'} = |0\rangle_Q \langle 0| \otimes e^{i\hat{p}_B x_0} + |1\rangle_Q \langle 1| \otimes e^{-i\hat{p}_B x_0}. \quad (37)$$

Clearly, if $\theta = 0$ the decoding unitaries (36), (37) are the inverse of the encoding ones (33), (34). They hence allow unit fidelity encoding/decoding if $\sigma^2 = 0$. However, if $\theta \neq 0$, there could be a nonzero optimal value of σ^2 .

The final qubit state is

$$\sigma_{Q'} = \mathcal{E}(|\varphi\rangle_Q \langle\varphi|) \quad (38)$$

$$= \text{Tr}_{B'} \left\{ V_2^{Q'B'} V_1^{Q'B'} (|0\rangle_Q \langle 0| \otimes \rho_{B'}) \right. \\ \left. \left(V_1^{Q'B'} \right)^\dagger \left(V_2^{Q'B'} \right)^\dagger \right\} \quad (39)$$

$$= [|a|^2(1 - \Pi_<) + |b|^2\Pi_>] |0\rangle_Q \langle 0| \\ + [|a|^2\Pi_< + |b|^2(1 - \Pi_>)] |1\rangle_Q \langle 1| \\ + (1 - \Pi_< - \Pi_>) (\bar{a}\bar{b}|0\rangle_Q \langle 1| + \bar{a}b|1\rangle_Q \langle 0|), \quad (40)$$

where

$$\Pi_< = \frac{1}{2} + \frac{1}{2} \text{erf} \left(\frac{\theta - x_0}{\sqrt{2\sigma^2}} \right), \quad (41)$$

$$\Pi_> = \frac{1}{2} - \frac{1}{2} \text{erf} \left(\frac{\theta + x_0}{\sqrt{2\sigma^2}} \right). \quad (42)$$

Then we can calculate the average channel fidelity

$$\langle \mathcal{F} \rangle = \int d\varphi_Q \langle \varphi | \sigma_{Q'} | \varphi \rangle_Q, \quad (43)$$

where $d\varphi$ is the uniform measure induced by the Haar measure on $SU(2)$.

Using (35), (36), (37), (38) and (43) we finally obtain

$$\langle \mathcal{F} \rangle = \frac{1}{2} + \frac{1}{4} \left[\text{erf} \left(\frac{\theta + x_0}{\sqrt{2\sigma^2}} \right) - \text{erf} \left(\frac{\theta - x_0}{\sqrt{2\sigma^2}} \right) \right]. \quad (44)$$

Then, we have the following proposition:

Proposition 4 (The forbidden interval) *The average channel fidelity $\langle \mathcal{F} \rangle$ shows a non-monotonic behavior as a function of σ iff $\theta \notin [-x_0, +x_0]$.*

Proof. We consider $\langle \mathcal{F} \rangle$ as a function of σ . We assume without loss of generality that $\theta > 0$. In order to have a non-monotonic behavior, we must check for the presence of a local maximum. The derivative $\frac{d\langle \mathcal{F} \rangle}{d\sigma^2}$ is as follows:

$$\frac{d\langle \mathcal{F} \rangle}{d\sigma^2} = \frac{e^{\frac{-\theta^2 - x_0^2}{2\sigma^2}}}{2\sigma^2 \sqrt{2\pi}} \left[(\theta + x_0) e^{\frac{-\theta x_0}{\sigma^2}} - (\theta - x_0) e^{\frac{\theta x_0}{\sigma^2}} \right]. \quad (45)$$

Then, the condition $\frac{d\langle \mathcal{F} \rangle}{d\sigma^2} = 0$ implies that

$$\frac{\theta - x_0}{\theta + x_0} = e^{\frac{-2\theta x_0}{\sigma^2}}, \quad (46)$$

which has the following unique solution:

$$\sigma_* = \sqrt{\frac{2\theta x_0}{\ln \left(\frac{\theta + x_0}{\theta - x_0} \right)}} \quad (47)$$

iff $\theta - x_0 > 0$. Finally, taking into account also the possibility that $\theta, x_0 < 0$, we conclude that a critical value of σ exists iff $\theta \notin [-x_0, +x_0]$. ■

FIG. 4: The average channel fidelity $\langle \mathcal{F} \rangle$ vs σ for $x_0 = 0.3$ and several values of θ , inside and outside the forbidden interval. From top to bottom, $\theta = 0.20$, $\theta = 0.25$, $\theta = 0.29$ (inside the forbidden interval), $\theta = 0.31$, $\theta = 0.35$, $\theta = 0.40$ (outside the forbidden interval).

Figure 4 shows $\langle \mathcal{F} \rangle$ as a function of σ for a given value of x_0 and several values of θ , both inside and outside the forbidden interval. A non-monotonic behavior is observed in the latter cases. It is worth noticing that the presence of noise can augment the average channel fidelity above the value of $2/3$, which is the threshold for quantum communication by measure-and-prepare protocols. Hence, in this sense, the presence of noise can lead to a transition between from a classical to a quantum regime in the average communication fidelity.

As shown in Figure 5, an analogous SR-like effect is observed in the same parametric region for the logarithmic negativity $LN = \log_2 \{ \text{Tr}[\mathcal{E} \otimes \mathcal{I}(|\Psi\rangle\langle\Psi|)]^\Gamma \}$ [25], where Γ indicates the partial transpose operation, $\mathcal{I}$ the identity map and $|\Psi\rangle$ a maximally entangled two-qubit Bell state. This quantity is the logarithmic negativity of the Choi-Jamiołkowski state associated to the quantum channel [17] and gives an upper bound on its two-way distillable entanglement (this latter quantity in turn equals the quantum capacity of a channel assisted by unbounded two-way classical communication [1]).

VI. CONCLUSION

In conclusion, we have determined necessary and sufficient conditions for noise benefits when transmitting classical and quantum information over a lossy bosonic channel or discriminating lossy channels (all of which have nonlinear coding or decoding processes). Specifically, we have considered a bit encoded into coherent states with different amplitudes that are subsequently sent through a lossy bosonic channel and decoded at the output by threshold measurement of their amplitudes (without and with the assistance of entanglement shared by sender and receiver). We have considered the discrimination of lossy bosonic channels having different loss parameters. In all

FIG. 5: The logarithmic negativity vs σ for $x_0 = 0.3$ and several values of θ inside and outside the forbidden interval. From top to bottom, $\theta = 0.20$, $\theta = 0.25$, $\theta = 0.29$ (inside the forbidden interval), $\theta = 0.31$, $\theta = 0.35$, $\theta = 0.40$ (outside the forbidden interval).

these cases, the performance is evaluated in terms of success probability (the complement of error probability to

one). It is worth remarking that the mutual information is a monotonic function of this probability, and so the same conclusions can be drawn in terms of mutual information.

SR effects appear whenever the threshold lies outside of the different forbidden intervals that we have established in our four propositions. If it lies inside of a forbidden interval, then the SR effect does not occur. Thus the SR effect should be useful in situations where the signals are so faint that they are indistinguishable within a finite measurement resolution. For instance, this is the case in homodyne detection, if the square of the average signal times the overall detection efficiency (which accounts for the detector's efficiency, the fraction of the field being measured, etc.) is below the vacuum noise strength [33].

Finally, we have also considered the transmission of quantum information, represented by a qubit which is encoded into the state of a bosonic mode and then decoded according to a threshold mechanism. The found SR effects, in terms of the average channel fidelity and of the output entanglement (quantified by the logarithmic negativity), represent a clear signature of noise benefits in quantum communication.
